Recent advances in the molecular diagnosis of tuberculosis

Wei-Juin Su

Division of Pulmonary Immunology and Infectious Diseases, Chest Department, Taipei Veterans General Hospital and School of Medicine, National Yang-Ming University, Taipei, Taiwan, ROC

Received: July 20, 2002 Accepted: August 1, 2002

To date, the diagnosis of tuberculosis has not improved significantly and still relies heavily on staining and culture of sputum or other clinical specimens which were developed more than 100 years ago. Staining does not differentiate tuberculosis from other mycobacterial infections, and culture requires at least 4 to 8 weeks. These are the major problems faced by tuberculosis control programs. In response to this demand, new rapid diagnostic methods are urgently sought. In recent years, much hope has been laid on the development of molecular techniques in the routine tuberculosis laboratory. This review concentrates on 4 techniques that are increasingly used in clinical laboratories: polymerase chain reaction to detect mycobacterial DNA in clinical specimens, nucleic acid probes to identify culture, restriction fragment length polymorphism analysis to compare strains for epidemiologic purposes, and genetic-base susceptibility testing methods for rapid detection of drug resistance. Finally, the increase in the use of clinically-useful molecular biological techniques that affect turnaround time, length of stay, and patient outcome, and reduce overall hospitalization costs will continue until universal standardization for molecular diagnostic procedures are provided. At present, conventional methods should not be replaced by novel methods until the latter are shown to be of equal or greater sensitivity, specificity, reliability, and user-friendliness. However, it is expected that the newly developed molecular techniques will complement our armamentarium of diagnostic tools in the detection of tuberculosis. It is also expected that clinical protocols based on molecular methods will increase the chances for cure by selecting the most appropriate treatment and improving the quality of life of tuberculosis patients.

Key words: Molecular diagnosis, tuberculosis, nucleic acid amplification, nucleic acid hybridization, polymerase chain reaction, restriction fragment length polymorphism

Mycobacterium tuberculosis is an important human pathogen, responsible for 2 billion people worldwide with latent infection, 8 million new cases a year, and up to 3 million annual deaths [1]. In the past decade, the increase in the prevalence of tuberculosis (TB), the emergence of multidrug-resistant strains, and the explosive interaction between *M. tuberculosis* and the human immunodeficiency virus have created public health urgency for early identification of *M. tuberculosis* infectious individuals and initiation of appropriate anti-TB chemotherapy [1-3]. Direct demonstration of acid-fast bacilli (AFB) in clinical specimens by Zeihl-Neelsen stain and isolation of *M. tuberculosis* by the conventional culture method, which were developed in the late 1800s and are the oldest tests still in clinical use, are considered gold standard for the laboratory diagnosis of TB infection [4]. Despite the long history of clinical application, limitations and controversy with regard to sensitivity and interpretation remain [5,6]. Significant effort is being made in the development of new techniques for the diagnosis of TB in order to overcome the limitations of currently available diagnostic methods. In the past 10 years, progress in molecular biology created new opportunities for development of new methods with an attempt to achieve the shortest turnaround time for clinical laboratory diagnosis [7,8]. In light of these findings, the use of molecular techniques for the laboratory diagnosis of *M. tuberculosis* and their clinical applications are reviewed.

Polymerase Chain Reaction

Amplification techniques, namely, the polymerase chain reaction (PCR) and its derivatives have attracted considerable interest as a diagnostic tool for TB, particularly with the hope of shortening the time required to detect and identify *M. tuberculosis* in respiratory specimens [8]. With the use of PCR, nucleic acid sequences unique to *M. tuberculosis* can be detected directly in clinical specimens, offering better

Corresponding address: Dr. Wei-Juin Su, Chest Department, Taipei Veterans General Hospital, 201, Section 2, Shih-Pai Road, Taipei, 11217, Taiwan, ROC. E-mail: wjsu@vghtpe.gov.tw

accuracy than AFB smear and greater speed than culture [9-11].

The PCR provides a means of amplifying DNA *in vitro* by the addition of the DNA polymerase and ribonucleotides and DNA specific for *M. tuberculosis* (primers). The amplification cycle is repeated many times, and in a short period millions of DNA fragments are readily detectable. Polymerase chain reaction has been used to detect *M. tuberculosis* in respiratory samples and other clinical samples. However, because laboratories that use PCR techniques have produced their own tests with a wide variety of primers, probes, methods of DNA extraction, PCR protocols, and detection methods, the clinical sensitivity of PCR compared with that of culture has been reported with wide variations [12]. These drawbacks may be improved by use of a commercially-available PCR kit, which has the potential for better overall performance characteristics in clinical laboratories. To date, 2 systems have been approved by the United States Food and Drug Administration (FDA) for use on smear-positive respiratory specimens: the Amplified Mycobacterium Tuberculosis Direct Test (MTD) (Gen-Probe, San Diego, CA, US) and the AMPLICOR *M. tuberculosis* Test (Roche Diagnostic Systems, Indianapolis, IN, US). Numerous studies have confirmed a sensitivity and specificity well over 95% in smear-positive respiratory specimens, but were much lower when testing smear-negative samples [13-15]. Recently, Gen-Probe modified the MTD with the aim of increasing sensitivity and decreasing turnaround time. The FDA approved this enhanced MTD in September 1999 for testing respiratory specimens, regardless of the smear result [16]. The experience in using commercial kits in Taiwan is limited. One report from Huang *et al* [17] found that the AMPLICOR kit had a sensitivity, specificity, positive predictive value, and negative predictive value of 73.81%, 97.18%, 93.94%, and 86.25%, respectively. Unfortunately, the performance of both tests on extrapulmonary specimens has varied [18,19], and neither of the manufacturers make claim that nonrespiratory specimens can be tested with their assay. To facilitate clinical application, laboratories must use in-house PCR for detection of extrapulmonary TB. Among the numerous amplification assays, IS*6110*-based methodologies become the most commonly used in-house PCR method in the clinical mycobacteriology laboratory [20]. IS*6110*, which belonging to the IS3 family, is found in virtually all members of the *M. tuberculosis* complex and is apparently restricted to this group of organisms [21,22]. We found evidence of IS*6110*-based methodologies in respiratory samples from patients in the Taipei Veterans General Hospital, Taiwan. The sensitivity and specificity compared with culture were 94.7% and 100%, respectively, and 76.7% and 98.6% for the smear-negative and culture-positive samples, respectively [23]. The overall sensitivity, specificity, positive predictive values, and negative predictive values compared with culture results were 91.7%, 98.6%, 98.8%, and 90.6%, respectively [23]. Although the high sensitivity and specificity of the in-house PCR is encouraging, there is a well-recognized interlaboratory variation in the results using PCR to detect the IS*6110* sequence [12]. At the current state of development, implementation of this novel method should take into account the performance of laboratories, the local epidemiologic situation, and should be based on cost-effective analysis [24].

Nucleic Acid Probe Methods

Nucleic acid probe tests are gaining importance in the identification of mycobacteria since the beginning of the 1990s when commercially-available nonradioactive (chemiluminescent) probes (Accuprobe; Gen-Probe, San Diego, CA, US) were introduced for rapidly identifying cultures at the species level. The use of nucleic acid probes for rapid identification of mycobacteria and maximizing cost effectiveness has been extensively reviewed [25,26]. Currently, 2 probe systems are available commercially. The Gen-Probe system uses a labeled DNA probe complementary to the ribosomal RNA in *M. tuberculosis*. Another available probe is designated SNAP (Syngene, San Diego, CA, US), which uses a probe labeled with alkaline phosphatase that is directed against ribosomal RNA. Originally, these probes were designed for culture confirmation of organisms, perhaps 10^5 organisms per sample, in a liquid or solid medium and are 99% to 100% specific [24,27]. Probes are also available for *Mycobacterium avium*, *Mycobacterium intracellulare*, *Mycobacterium avium* complex, *Mycobacterium gordonae*, and *Mycobacterium kansasii* [24]. An additional advantage of these probes is the shelf life of 6 to 12 months. Therefore, the nucleic acid probes alone or in combination with other identification methods are used widely in routine clinical practice, which serve as a substitute for biochemical testing to identify mycobacterial species and are more accurate than biochemical methods. The only drawback reported is the detection limits of approximately 105 organisms per reaction tube, which will require to culture the specimens long enough to get such a large number of organisms.

Molecular Typing of *M. tuberculosis*

Key factors in the fight against TB are rapid detection, adequate therapy, and contact tracing to arrest further transmission. Recent developments in molecular technologies have led to methods for rapid tracing of TB transmission routes by differentiating clinical isolates based on polymorphism in genomic DNA of *M. tuberculosis* [28]. Furthermore, DNA fingerprinting of *M. tuberculosis* provides a versatile tool for the identification of transmission [29], investigation of TB outbreaks [30,31], distinction between reactivation and reinfection [32], as well as proof of laboratory cross-contamination [33,34]. The most commonly used method for genetic typing of *M. tuberculosis* complex strains is restriction fragment length polymorphism (RFLP) analysis, by Southern blotting of genomic DNA and the mobile element IS*6110* as a probe [35]. IS*6110*-based RFLP has shown a high degree of heterogeneity in typing patterns and reproducibility [36], which has become the standard method for fingerprinting of *M. tuberculosis* (Fig. 1). However, it has been hampered by the need to culture this slow-growing organism and by the level of technical sophistication needed for RFLP typing [35,37].

Other types of multicopy DNA such as direct repeat (DR) sequences [38], spacer oligotides between the DR sequences (spoligotyping) [39], and polymorphic GC-rich repetitive sequences (PGRS) [40] have been used as a secondary probe in subdividing clusters of *M. tuberculosis* with fewer IS*6110* copies [41] or in differentiating *Mycobacterium bovis* isolates from animals [29].

Genotypic Methods for Drug Susceptibility Testing

Appropriate therapeutic decisions are based on the result of anti-TB drug susceptibility testing. Traditional susceptibility tests are not only time-consuming, but have also significant technical problems in their standardization [42]. Recently developed molecular biological techniques have significantly helped in understanding the basis of drug action and resistance mechanisms in *M. tuberculosis* [43,44]. In the case of rifampicin, for example, 95% of resistance is caused by mutations in the *rpo*B gene, which codes for a subunit of the DNA-dependent RNA polymerase enzyme [45]. Molecular tests have been designed to detect mutations in *rpo*B gene responsible for rifampicin resistance [46-50]. Recently, we have successfully demonstrated that susceptibility testing of *M. tuberculosis* to rifampicin could be accomplished rapidly with acceptable accuracy by PCR-reverse dot blot (RDB) hybridization (Table 1). The results of PCR-RDB assay are available within one day, while the proportion method requires 3 weeks to complete. Similar approaches have been used to detect resistance to other anti-TB agents [51,52]. Unfortunately, resistance to anti-TB drugs involves changes in multiple genes and at multiple potential locations. In addition, not all possible genes or mechanisms of resistance have been identified. These make testing for the various genes difficult and represent a significant drawback for diagnostics. Given the complexity of genotypic methods, there has been interest in high-density probe arrays (gene chips) that would facilitate screening for mutations in an amplified product [53-55]. Research is still in progress to develop rapid tests for drug resistance that are suitable for use in the routine TB laboratory.

Fig. 1. IS*6110*-based DNA fingerprint patterns from isolates of *M. tuberculosis* from patients in the tuberculosis ward in Taipei Veteran General Hospital. Molecular weight markers are along both margins. The number and position of the bands varies

What is the Appropriate Use of the Rapid Diagnostic Tests for TB?

In clinical practice, the use of molecular testing for the diagnosis of TB, in combination with "classic" diagnostic tools, can greatly enhance the diagnostic ability of pulmonary clinicians, particularly in paucibacillary infections and in patients with atypical presentation, such as immunodeficient individuals. We now need to ask what is the appropriate use of the molecular diagnostic tests for TB. This question cannot yet be definitively answered, because these tests do not yet perform ideally in all circumstances. Clinicians must be careful in correlating the molecular test results with the clinical aspects of each case; sometimes multiple testing or alternative types of information are of great value. With appropriate use, they can improve the accuracy in diagnosing TB, and cut the spread of TB in the community and thus the costs of health care.

Table 1. Sensitivity and specificity of PCR-RDB hybridization in detection of rifampicin resistance from clinical isolates

PCR-RDB result	Results of proportion method		Sensitivity, %	Specificity, %
	Resistant strains	Susceptible strains		
Mutant type	33	0	100	100
Wile type	0	72		

Abbreviation: PCR-RDB = polymerase chain reaction-reverse dot blot

Conclusions

The mycobacteriology laboratory of today has a critical role in the control of TB by rapid turn-around times, allowing for the provision of optimal medical care, infection control, and public health management of TB patients. Much is expected from molecular biology techniques for the rapid, sensitive, and specific diagnosis of TB. However, the necessary resources and expertise are seldom available in clinical practice. Furthermore, quality control problems and the lack of standardization render molecular techniques unreliable in the hands of the inexperienced. After all, the performance of a good test relies on its user, and the whole medical community should not be deprived of the use of these novel rapid molecular methods because of its poor use in the hand of a few clinicians. We are only beginning to understand how to use these new tests, which cannot replace the traditional smears and cultures. It is promising that molecular technologies will take us to a new era of advanced, effective, and rapid diagnosis of TB, and in response to this, committees of experts should provide the medical community with guidelines on how to appropriately use molecular techniques for diagnosing of TB. Finally, cost-effectiveness and economic constraints also require careful consideration, as these techniques are expensive.
